Abstract. Delayed effects are important in modeling biological systems, and timed Boolean networks have been proposed for such a framework. Yet it is not an easy task to design such Boolean models with delays precisely. Recently, an attempt to learn timed Boolean networks has been made in [11] in the framework of learning state transition rules from time-series data. However, this approach still has two limitations: (1) The maximum delay has to be given as input to the algorithm; (2) The possible value of each state is assumed to be Boolean, i.e., two-valued. In this paper, we extend the previous learning mechanism to overcome these limitations. We propose an algorithm to learn multi-valued biological models with delayed influence by automatically tuning the delay. The delay is determined so as to minimally explain the necessary influences. The merits of our approach is then verified on benchmarks coming from the DREAM4 challenge.

Keywords: dynamical systems, multi-valued models, delay, Markov(k), learning from interpretation transition, inductive logic programming

1 Introduction

In some biological and physical phenomena, effects of actions or events appear at some later time points. For example, delayed influence can play a major role in various biological systems of crucial importance, like the mammalian circadian clock [5] or the DNA damage repair [1]. While Boolean networks have proven to be a simple, yet powerful, framework to model and analyze the dynamics of the above examples, they usually assume that the modification of one node results in an immediate activation (or inhibition) of its targeted nodes [2] for the sake of simplicity. But this hypothesis is sometimes too broad and we really need to capture the memory of the system i.e., keep track of the previous steps, to get a more realistic model. Our work aims to give an efficient and valuable approach to learn such dynamics. In some previous works, Markov(1) state transition systems are represented with logic programs [7], in which the state of the world is represented by an Herbrand interpretation and the dynamics that rule the environment changes are represented by a logic program $P$. The rules in $P$...
represent some variable of the system and \( \text{val}_i \) annotated logics, the atom \( \text{var}_i \) is said to be annotated by the constant \( \text{val} \). We consider a multi-valued logic program as a set of rules of the form
\[
\text{var}^{\text{val}} \leftarrow \text{var}_1^{\text{val}_1} \land \cdots \land \text{var}_n^{\text{val}_n}
\]
(1)
where \( \text{var}^{\text{val}} \) and \( \text{var}_i^{\text{val}_i} \)'s are atoms \( (n \geq 1) \). For any rule \( R \) of the form (1), the atom \( \text{var}^{\text{val}} \) is called the head of \( R \) and is denoted as \( h(R) \), and the conjunction to the right of \( \leftarrow \) is called the body of \( R \). We represent the set of literals in the body of \( R \) of the form (1) as \( b(R) = \{ \text{var}_1^{\text{val}_1}, \ldots, \text{var}_n^{\text{val}_n} \} \). A rule \( R \) of the form (1) is interpreted as follows: the variable \( \text{var} \) takes the value \( \text{val} \) in the next state if all variable \( \text{var}_i \) have the value \( \text{val}_i \) in the current state. An interpretation of a multi-valued program provides the value of each variable of the system and is defined as follows.

Definition 1 (Multi-valued interpretation). Let \( \mathcal{B} \) be a set of atoms where each element has the form \( \text{var}^{\text{val}} \). An interpretation \( I \) of a set of atoms \( \mathcal{B} \) is a subset of \( \mathcal{B} \) where \( \forall \text{var}^{\text{val}} \in \mathcal{B}, \text{var}^{\text{val}} \in I \) and \( \forall \text{var}^{\text{val}} \in I, \exists \text{var}^{\text{val}'} \in I, \text{val} \neq \text{val}' \).

For a system \( S \) represented by a multi-valued logic program \( P \) and a state \( s_1 \) represented by an interpretation \( I \), the successor of \( s_1 \) is represented by the interpretation:
\[
\text{next}(I) = \{ h(R) \mid R \in P, b(R) \subseteq I \}
\]
The state transitions of a logic program \( P \) are represented by a set of pairs of multi-valued interpretations \( (I, \text{next}(I)) \).
Definition 2 (Multi-valued consistency). Let \( R \) be a rule and \((I, J)\) be a state transition. \( R \) is consistent with \((I, J)\) iff \( b(R) \subseteq I \) implies \( h(R) \in J \). Let \( E \) be a set of state transitions, \( R \) is consistent with \( E \) if \( R \) is consistent with all state transitions of \( E \). A logic program \( P \) is consistent with \( E \) if all rules of \( P \) are consistent with \( E \).

The notion of subsumption among rules is formally the same as for the Boolean case. We say that a rule \( R_1 \) is more general than another rule \( R_2 \) if \( b(R_1) \subseteq b(R_2) \). In particular, a rule \( R \) is most general if there is no rule \( R'(\neq R) \) that subsumes \( R \) (\( b(R) = \emptyset \)). To learn multi-valued logic programs with \textbf{LF1T} we need to adapt the least specialization of [10] to handle non-Boolean variables.

Definition 3 (Multi-valued least specialization). Let \( R_1 \) and \( R_2 \) be two rules such that \( h(R_1) = h(R_2) \) and \( R_1 \) subsumes \( R_2 \). Let \( B \) be a set of atoms. The least specialization \( \text{ls}(R_1, R_2, B) \) of \( R_1 \) over \( R_2 \) w.r.t \( B \) is

\[
\text{ls}(R_1, R_2, B) = \{ h(R_1) \leftarrow b(R_1) \land \text{\textit{var}}^{\text{val}'} | \text{\textit{var}}^{\text{val}} \in b(R_2) \setminus b(R_1), \text{\textit{var}}^{\text{val}'} \in B, \text{\textit{val}'} \neq \text{\textit{val}} \}
\]

Least specialization can be used on a rule \( R \) to avoid the subsumption of another rule with a minimal reduction of the generality of \( R \). By extension, least specialization can be used on the rules of a logic program \( P \) to avoid the subsumption of a rule with a minimal reduction of the generality of \( P \). Let \( P \) be a logic program, \( B \) be a set of atoms, \( R \) be a rule and \( S \) be the set of all rules of \( P \) that subsume \( R \). The least specialization \( \text{ls}(P, R, B) \) of \( P \) by \( R \) w.r.t \( B \) is as follows:

\[
\text{ls}(P, R, B) = (P \setminus S) \cup ( \bigcup_{R_P \in S} \text{ls}(R_P, R, B))
\]

3 Multi-valued Markov\((k)\) systems

In this section, we recall the formalization of [11] about Markov\((k)\) systems and adapt it to multi-valued variables. A Markov\((k)\) system can be seen as a \(k\)-steps deterministic system. In other words, the state of the system may depend on its (at most) \( k \) previous states, i.e., for any sequence of \( k \) state transitions there is only one possible state at time step \( k + 1 \). If a system is Markov\((k)\), it means that \( k \) is the maximum number of time steps such that the influence of any component (e.g., a gene) on another component is expressed. In other words, the state of a system may then depend on its (at most) \( k \) previous states.

Definition 4 (Timed Herbrand Base). Let \( P \) be a logic program. Let \( B \) be the Herbrand base of \( P \) and \( k \) be a natural number. The timed Herbrand Base of \( P \) (with period \( k \)) denoted by \( B_k \), is as follows:

\[
B_k = \bigcup_{i=1}^{k} \{ \text{\textit{var}}^{\text{val}'}_i | \text{\textit{var}}^{\text{val}} \in B \}
\]

where \( t \) is a constant term which represents the current time step.

According to Definition 4, given a propositional atom \( \text{\textit{var}}^{\text{val}} \), \( \text{\textit{var}}^{\text{val}'} \) is a new propositional atom for each \( j = t−i \), \((0 \leq i \leq k)\). A Markov\((k)\) system can then be interpreted as a logic program as follows.

Definition 5 (Markov\((k)\) system). Let \( P \) be a logic program, \( B \) be the Herbrand base of \( P \) and \( B_k \) be the timed Herbrand Base of \( P \) with period \( k \). A Markov\((k)\) system \( S \) with respect to \( P \) is a logic program where for all rules \( R \in S \), \( h(R) \in B \) and all atoms appearing in \( b(R) \) belong to \( B_k \).
In a Markov$(k)$ system $S$, the atoms that appear in the body of the rules represent the value of the atoms that appear in the heads, but at previous time steps. In a context of modeling gene regulatory networks, these latter atoms represent the concentration of the interacting genes. This concentration is abstracted as an integer value modeling the fact that it is lower or greater than certain thresholds. Trace of executions, their consistency and $k$-step interpretations are formally equivalent to the Boolean case formalized in [11].

4 Algorithm

In [11] we proposed a method to learn delayed influences of Boolean systems: the LFkT algorithm. LFkT is an algorithm that can learn the dynamics of a Markov$(k)$ system from its traces of execution. LFkT takes a set of traces of executions $O$ as input, where each trace is a sequence of state transitions. If $O$ is consistent, the algorithm outputs a logic program $P$ that realizes all transitions of $O$. In this section, we propose a new version of this algorithm that handle multi-valued variables. Furthermore, the delays are now computed dynamically and do not need to be known or fixed to the size of the longest trace.

LFkT:

- **Input**: A set of traces of executions $O$ of a multi-valued Markov$(k)$ system $S$.
- **Step 1**: Initialize a logic program with fact rules.
- **Step 2**: Pick a trace $T$ from $O$ and update the delay considered accordingly.
  - Initialize a logic program with fact rules for each new delay.
  - Revise these logic programs with all previous traces (like step 3).
- **Step 3**: Convert the trace into interpretation transitions and revise the logic programs using least specialization.
- **Step 4**: If there is remaining trace in $O$, go back to step 2.
- **Step 5**: Merge all logic programs into one while avoiding rules subsumption.
- **Output**: A set of rules which realizes $O$.

The detailed pseudo code of LFkT is given as appendix in Algorithm 1.

Theorem 1 (Correctness of LFkT). Let $P$ be a logic program, $\mathcal{B}$ be the Herbrand base of $P$ and $\mathcal{B}_k$ be the timed Herbrand base of $P$ with period $k$. Let $S$ be a Markov$(k)$ system with respect to $P$. Let $O$ be a set of traces of $S$. Using $O$ as input, LFkT outputs a logic program that realizes all consistent traces of $O$. Proof is given in appendix.

Theorem 2 (Complexity). Let $P$ be a logic program, $\mathcal{B}$ be the Herbrand base of $P$ and $\mathcal{B}_k$ be the timed Herbrand base of $P$ with period $k$. Let $S$ be a multi-valued Markov$(k)$ system with respect to $P$. Let $n$ be the number of variable of $S$. Let $v$ be the maximal number of value of a variable of $S$. Let $O$ be a set of traces of execution of $S$. The complexity of learning $S$ from $O$ with LFkT is respectively: $O(n \cdot v^{nk+1} + |O|)$ for memory and $O(\sum_{T \in O} |T| \cdot n^{nk+3} + |O| \cdot n^2k^2 + n \cdot v^{nk+2} + n \cdot v^{nk+1} \cdot |O| \cdot k)$ for runtime. Proof is given in appendix.

5 Evaluation

In this section, we assess the efficiency of our new LFkT algorithm through case studies coming from the DREAM4 challenge [9].

DREAM challenges are annual reverse engineering challenges that provide biological case studies. In this paper, we focus on the datasets coming from DREAM4. The input data that we tackle here consists of the following: 5 different systems each composed of 10 genes, all coming from E. coli and yeast networks. For every such system, the available data are the following: (i) 5 time series data with 21 time points; (ii) steady state at wild type; (iii) steady states after knocking out each gene; (iv) steady
states after knocking down each gene (i.e. forcing its transcription rate at 50%); (v) steady states after some random multifactorial perturbations. We processed all the data. Because of the lack of space, we focus here on the management of time series data.

5.1 Settings

Time series data provide us 20 transitions. Each of them include different perturbations that are maintained all time along during the first 10 transitions and applied to at most 3 genes. In this setting, a perturbation means a significant increase or decrease of the gene expression. In the raw data of the time series, gene expression values are given as real number between 0 and 1. To apply our approach, we chose to discretize those data into 4 qualitative values. Each gene is discretized in an independent manner, with respect to the following procedure: we compute the average value of the gene expression among all data of a time series, then the values between the average and the maximal/minimal value are divided into as many levels. Discretizing the data according to the average value of expression is expected to reduce the impact of perturbation on the discretization and thus on the rules that are learned.

5.2 Results

Table 1 shows the evolution of runtime, output size and precision of prediction of LFkT on the five benchmarks of the DREAM4 challenge. Here, we use LFkT to learn rules independently for each time series. The rules learned on one time series are evaluated on the others series in a cross-validation manner. The precision of each rule is computed as the ratio between the number of times they match a transition and how many transitions they realize. For a transition \((I, J)\) when \(b(R) \subseteq I\), the rule \(R\) matches the transition and if \(h(R) \in J\), \(R\) realizes the transition. To use the model learned to predict the next state of the system we simply apply the rules with the best ratio that matches the current state. By doing so, we expect to reduce the impact of the perturbations on the predictions of the model learned.

The number of generated rules is huge, but the following simple heuristics can be used to greatly reduce it. First, rules that never realize any transitions can be discarded. Rules that are subsumed by rules with a better or equal precision are discarded. This allows to remove about 50% of the rule generated. We can also detect and discard rules that will never be used for prediction: the rules that never have a better precision than an other rule that matches a same state with a different conclusion. This allows to remove about 99% of the remaining rules. Using those simple heuristics does not impact the dynamic of the model that is learned: the prediction will be exactly the same. But it simplifies the model that is learned and makes it more human readable.

The run time showed in Table 1 includes: learning, cross-validation and applications of the heuristics. All experiments are run with a C++ implementation of LFkT on a processor Intel Xeon (X5650, 2.67GHz) with 12GB of RAM.

The DREAM4 challenge offers two different problems, which consist in predicting (i) the structure of the gene interactions (in terms of an unsigned directed graph); (ii) attractors in some given conditions. So far, LFkT is not designed to efficiently
tackle the first issue. Indeed, LFIT method focuses on the learning of the dynamics of the observed system. This means that the rules learned by LFkT will be recurrent patterns, i.e., correlations between the evolution of values of the different variables. This method however can be fully applied to predict attractors. For this evaluation, we are given an initial state and 5 different dual gene knockouts conditions. The goal is to predict the attractor in which the system will fall from the initial state for each dual knockout. In the challenge, the quality of the prediction is evaluated by computing the mean square error between the predicted state and the expected one. The precision we achieved in these experiments is quite good considering the results of the competitors of the DREAM4 challenge [6]. Their results range between 0.01 and 0.075 for the same evaluation settings, which we are comparable to.

We plan to pursue these evaluations. Competitors of DREAM4 Challenge tackled not only the networks with 10 genes, but also the ones consisting of 100 genes with no drastic loss of precision. In this on-going work, we now consider applying our approach to these large networks, to get stronger arguments in favor of our approach. Furthermore, [6] showed much better prediction results (0.01 to 0.025), when changing the given initial state for the one based on single gene knockout. We should also consider to discuss this issue in future works in order to improve our method, which obtained encouraging first results as showed in this subsection.

6 Conclusion
In this paper, we propose a twofold extension of our previous results to learn normal logic programs from interpretation transitions on k-steps: (i) Delay is now dynamically adjusted and does not need to be initially assumed as input.; (ii) The learning algorithm natively tackles multi-valued models. The work can then be directly applied to the learning of Boolean and multi-valued discrete networks with delayed influences, which is crucial to understand the memory effect involved in some interactions between biological components. Further works aim at performing a comprehensive evaluation of our approach on data coming from DREAM4 challenge (and further iterations of this challenge). This would contribute to assess the merits of our approach for biologists. We should also consider connecting through various databases in order to extract real time series data, and subsequently explore and use them to learn genetic regulatory networks. We also consider extending the methodology to asynchronous semantics, which can help to capture more realistic behaviors.

12: return delay

Algorithm 3 learn\((P, T, \text{min\_delay}, B)\) : Revise \(P\) to avoid the subsumption of \(R\)

1: INPUT: \(P\) a vector of logic program, \(T\) a trace of execution and \(\text{min\_delay}\) an integer
2: OUTPUT: a vector of logic program

3: \(E := \text{interpret}\(e\)(\(T\))
4: for each \(i\) from \(\text{min\_delay}\) to \(|T|\) do
5:    for each \(k\)-step interpretation \((I, J) \in E\) with \(k \geq i\) do
6:       remove from \(I\) all atoms \(\text{var}_{i-n}\) with \(n > i\)
7:       for each atom \(\text{var}_{\text{val}_I} \in J\) do
8:          for each \(\text{var}_{\text{val}'_I} \in B\), \(\text{val}'_I \neq \text{val}\) do
9:             \(R_{\text{var}_{\text{val}'_I}} := \bigwedge_{l_j \in I} l_j\)
10:        \(P_i := \text{Specialize}(P_i, R_{\text{var}_{\text{val}'_I}}, B)\)
11: return \(P\)

1) The algorithm starts with a logic program that only contains all possible fact rules and assumes that the system to learn is Markov(1) (lines 6-9). These different programs are merged at the end to constitute a logic program that realizes all consistent traces of \(O\). 

2.1) Before learning from a trace, we need to guarantee that we are considering a valid delay according to the trace (lines 13-20). That is why we check the minimal delay required to explain the trace by using the delay function, whose pseudo code is given in Algorithm 2. If this delay is greater than the one currently considered by the algorithm, it updates this delay and generates programs for all missing delays (lines 14-20). All previously analyzed traces are then re-analyzed but only for these new programs. This allows to learn only the missing delayed rules. 

2.2) Then it checks the consistency of the new trace with previously analyzed ones (lines 21-31). The delay considered is increased if necessary. In practice, the consistency of the new traces with previously analyzed ones can be directly checked from the programs that are learned. If the program that considers the biggest delay \(k\) has no rule that can realize the last transition of \(T\) (if \(\exists R \in P_k, b(R) \subseteq I\) with \((I, S_n) := \text{the} \ |T|-\text{step interpretation transition of} \ T\)), then the trace is not \(k\)-consistent with at least one of the previous ones. 

2.3) The program that is learned is revised according to the new trace using least specialization (lines 34-37). In order to use least specialization, we need to convert the trace of execution into interpretation transitions. This conversion is done by the function interpret, whose pseudo code is given in Algorithm 4. Here, \(\text{min}(k, |T|)\) interpretation transitions are extracted from the trace, one for each possible delay inferior to the currently considered one, that is \(k\). Following this method, it produces
one \( \min(k, |T|) \)-step interpretation, one \( \min(k, |T|) - 1 \) interpretation, \ldots, one 1-step interpretation. The function outputs them as a vector of interpretation transitions \( E \), where each \( E_i \) corresponds to an \( i \)-step interpretation transition of a sub-trace of size \( i \) of \( T \). The algorithm iteratively learns from each pair of interpretations of \( E \). Now it

\begin{algorithm}
\caption{interpret\( T \)\( )\) : Extract interpretation transitions from a trace}
\begin{algorithmic}[1]
\STATE \textbf{INPUT:} a trace of execution \( T = (S_0, \ldots, S_n) \)
\STATE \textbf{OUTPUT:} \( E \) a set of pairs of interpretations
\STATE \( E := \emptyset \)  \\

\STATE \( I := \emptyset \)
\FOR {each state \( s' \) before \( s_k \) in \( T' \)}
\STATE \( \text{delay} := k - k' \)
\FOR {each atom \( a \) \in \( s' \)}
\STATE \( I := I \cup \{ a_{\text{delay}} \} \)
\ENDFOR
\STATE \( E := E \cup (I, S_k) \)
\ENDFOR
\ENDFOR
\STATE \textbf{return} \( E \)
\end{algorithmic}
\end{algorithm}

only needs to apply the least specialization by analyzing each pair of interpretations \( (I, J) \in E \). For each atom \( \text{var}^{\text{val}} \) that \textbf{does not appear} in \( J \), it infers an \textbf{anti-rule:} \( R_{\text{var}^{\text{val}}} := \text{var}^{\text{val}} \leftarrow \bigwedge_{B_i \in I} B_i \). Then, least specialization is used to make each corresponding logic program \( P'_i \) consistent with \( R_{\text{var}^{\text{val}}} \), according to the delay of interpretation transition. Algorithm 5 shows the pseudo code of this operation. In the

function \textbf{specialize}, it first extracts all rules \( R_P \in P \) that subsumes \( R_{A_i} \). It generates the least specialization of each \( R_P \) by generating a rule for each literal in \( R_{A_i}^{val} \). Each rule contain all literals of \( R_P \), plus a literal that represents another value of the variable
represented by a literal in $R_{\text{var}}^I$, so that $R_{\text{var}}^I$ is not subsumed anymore by that rule. Then \textit{specialize} adds in $P$ all the generated rules that are not subsumed by $P$, so that $P$ becomes consistent with the transition $(I, J)$.

3) After analyzing all traces of $O$, the $k$ programs that have been learned are merged into a unique logic program while taking care that subsumed rules are discarded. 4) All rules that are not necessary to explain the observations are discarded. The algorithm only keeps the rules that can be used to realize at least one of the transition of the input traces. Finally, \textbf{LFkT} outputs a logic program that realizes all consistent traces of execution of $O$.

\subsection{Proof of Theorem 1 (Correctness of LFkT)}

Let $P$ be a logic program, $B$ be the Herbrand base of $P$ and $B_k$ be the timed Herbrand base of $P$ with period $k$. Let $S$ be a Markov($k$) system with respect to $P$. Let $O$ be a set of traces of $S$. Using $O$ as input, \textbf{LFkT} output a logic program that realizes all consistent traces of $O$.

\textit{Proof.} Let $V$ be the vector of interpretation transition extracted from $O$ by \textbf{LFkT} (Algorithm 4). According to Theorem 4 of [10], initializing \textit{LFIT} with $\{p \mid p \in B\}$, by using minimal specialization iteratively on a set of interpretation transitions $E$, we obtain a logic program $P$ that realizes $E$. Since \textbf{LFkT} uses this method on each element of $V$, \textbf{LFkT} learns a vector of logic programs $P'$ such that each logic program $p'_0 \in P'$ realizes the corresponding set of interpretation transitions $v_n \in V$, $n \geq 1$.

Let $p'_n \in P'$ be the logic program learn from $v_n \in V$, $n \geq 1$. $p'_n$ is obtained by minimal specialization of $\{p \mid p \in B\}$ with all anti-rule of $v_n$ (non consistent rule). According to Theorem 3 of [10], $p'_n$ does not subsume any anti-rule that can be inferred from $v_n$. Then, $p'_n$ realizes all deterministic transition of $v_n$, that is $\forall (I, J) \in v_n$, / $\exists (I, J'), J \neq J'$.

Since $v_n$ contains $n$-step interpretation transition that represent all sub-traces of size $n$ of $O$, $p'_n$ realizes all consistent sub-trace of size $n$ of $O$. Let $P_{n-1}$ be a logic program that realizes all consistent sub-traces of size at most $n-1$ of $O$. $p'_n$ can contain a rule $R$ such that $(B_n \setminus B_{n-1}) \cap b(R) = \emptyset$ (no literal of $R$ refers to the $t-n$ state of the variables). In this case $R$ realizes a sub-trace of size $n$ and also some sub-traces of size at most $n-1$. If these sub-traces of size $n-1$ are consistent, then they are necessary realized by $P_{n-1}$. $P_{n-1} \cup \{R\}$ does not realize more consistent sub-trace of size at most $n-1$ than $P_{n-1}$. Let $S_R$ be the set of rules of $p'_n$ of the form $R$, then $(p'_n \setminus S_R)$ only realizes all sub-traces of size $n$ of $O$. Then the logic program $P_k = P_{n-1} \cup (p'_n \setminus S_R)$ only realizes all consistent sub-trace of size at most $n-1$ of $O$ and all sub-traces of size $n$ of $O$, that is $P_k$ realizes all consistent sub-traces of size at most $n$ of $O$.

Let $p_1' \in P'$ be the logic program learned from $v_1 \in V$, and let $P = p_1'$. Let $R'$ be all rules of the logic program $p'_n$ such that $(B_n \setminus B_{n-1}) \cap b(R') \neq \emptyset$. Iteratively adding rules $R'$ into $P$, starting by the logic program $P_1$ until $P_k$, we obtain a logic program that realizes all consistent sub-traces of size at most $k$ of $O$. As a result, using $O$ as input, \textbf{LFkT} outputs a logic program that realizes all consistent traces of $O$. \hfill $\square$

\subsection{Proof of Theorem 2 (Complexity of LFkT)}

Let $P$ be a logic program, $B$ be the Herbrand base of $P$ and $B_k$ be the timed Herbrand base of $P$ with period $k$. Let $S$ be a multi-valued Markov($k$) system with respect to $P$. Let $n$ be the number of variables of $S$. Let $v$ be the maximal number of values of a variable of $S$. Let $O$ be a set of traces of execution of $S$. The complexity of learning $S$ from $O$ with \textbf{LFkT} is respectively: \textit{O}($n \cdot v^{nk+1} + |O|$) for memory and $O(\sum_{T \in O} |T| \cdot n v^{nk+2} + |O| \cdot n^2 k^2 + n \cdot v^{nk+2} + n \cdot v^{nk+1} \cdot |O| \cdot k$) for runtime.
Proof. \( n \) is the number of possible heads of rules of \( S \). \( nk \) is the maximum size of a rule of \( S \), i.e. the number of literals in the body; a literal can appear at most one time in the body of a rule. For each rule head of \( B \) there are \( v^{nk} \) possible bodies: each literal can be present or absent from the body. From these preliminaries we conclude that the size of a Markov(\( k \)) system \( S \) learned by \( LFkT \) is at most \( |S| = n \cdot v^{nk} \). To learn \( S \), \( LFkT \) needs to store \( k \) programs \( P_i \) that are Markov(\( i \)) system with respect to \( P \), \( 1 \leq i \leq k \). The algorithm also needs to store the previously analyzed traces in order to update the considered delay.

**Conclusion 1:** the memory use of \( LFkT \) is \( O(\sum_{i=1}^{k} |P_i| + O) = O(k \cdot \frac{n \cdot v^{nk}}{k} + |O|) \) that is bound by \( O(n \cdot v^{nk+1} + |O|) \).

For each trace \( T \) of \( O \), \( LFkT \) extracts \( |T| \) pairs of interpretations. For each pair of interpretation \((I, J)\), \( LFkT \) infers an anti-rule rule \( R^j_a \) for each \( A \in B, A \not\in J \). \( LFkT \) compares each \( R^j_a \) with all rules of each programs \( P_i \). There is at most \( |B| - n \) anti-rules that can be inferred from \((I, J)\) by \( LFkT \) and the size of each program \( P_i \) is bound by \( O(\frac{n \cdot v^{nk}}{k}) \). Then, the complexity of learning one trace of execution \( T \in O \) with \( LFkT \) is \( O(|T| \cdot |B| - n \cdot k \cdot |P_i|) = O(|T| \cdot n^2 - n \cdot k \cdot \frac{n \cdot v^{nk}}{k}) = O(|T| \cdot n^2 v^{nk+2} - n) \) that is bound by \( O(|T| \cdot n^2 v^{nk+3}) \). To update the considered delay, the algorithm has to check the delay of each new trace \( T \), this operation belongs to \( O(|T|^2) = (n^2 k^2) \). And, checking the consistency of a new traces with previous analyzed ones is bound by \( O(|O| \cdot n^2 k^2) \).

Merging the programs requires to compare all rules to detect subsumption, it has a complexity of \( O(n \cdot v^{nk+2}) \). Finally, removing the rules that are not necessary to realize \( O \) requires to compare each rule with all \( k \)-step interpretations of \( O \), thus it requires \( O(n \cdot v^{nk+1} \cdot |O| \cdot k) \).

**Conclusion 2:** The complexity of learning \( S \) from \( O \) with \( LFkT \) is \( O(\sum_{T \in O} |T| \cdot n^2 v^{nk+3} + |O| \cdot n^2 k^2 + n \cdot v^{nk+2}) \).

\( \square \)
